Received 1997 July 14; accepted 1997 September 10

ABSTRACT

We present spectroscopic and photometric observations of the luminous narrow-line Type IIP (plateau) supernova 1994W. After the plateau phase ($t \gtrsim 120$ days), the light curve dropped by ~ 3.5 mag in V in only 12 days. Between 125 and 197 days after explosion, the supernova faded substantially faster than the decay rate of ^{56}Co , and by day 197 it was 3.6 mag less luminous in R than SN 1987A. The low R luminosity could indicate $\lesssim 0.0026^{+0.0017}_{-0.0011} M_{\odot}$ of ^{56}Ni ejected at the explosion. The emission between 125 and 197 days would in this case be dominated by diffusion of emission from the mantle region, or by an additional power source, presumably circumstellar interaction. Alternatively, the late light curve could have been dominated by ^{56}Co decay. In this case, the mass of the ejected ^{56}Ni would have been $0.015^{+0.012}_{-0.008} M_{\odot}$, and the rapid fading between 125 and 197 days most likely due to dust formation. Although this value of the mass is higher than in the first case, it is still lower than estimated for any previous Type II supernova.

Only progenitors with $M_{\text{ZAMS}} \sim 8\text{--}10 M_{\odot}$ and $M_{\text{ZAMS}} \gtrsim 25 M_{\odot}$ are expected to eject such low masses of ^{56}Ni . If $M_{\text{ZAMS}} \sim 8\text{--}10 M_{\odot}$, the plateau phase indicates a low explosion energy, while for a progenitor with $M_{\text{ZAMS}} \gtrsim 25 M_{\odot}$, the energy can be the canonical $\sim 10^{51}$ ergs. As SN 1994W was unusually luminous, the low-mass explosion may require an uncomfortably high efficiency in converting explosion energy into radiation. This favors a $M_{\text{ZAMS}} \gtrsim 25 M_{\odot}$ progenitor.

The supernova's narrow ($\sim 1000 \text{ km s}^{-1}$) emission lines were excited by the hot supernova spectrum, rather than by a circumstellar shock. The thin shell from which the lines originated was most likely accelerated by radiation from the supernova.

1. INTRODUCTION

Type II supernovae (SNe II) are thought to arise from the explosion of massive (zero-age main-sequence mass $M_{\text{ZAMS}} \gtrsim 8\text{--}10 M_{\odot}$) stars that end their lives with a substantial fraction of hydrogen in their envelopes. The explosion is triggered by the collapse of the progenitor's core. The best-understood core-collapse events are SN IIP (plateau), whose light curves are nearly flat during the first $\sim 2\text{--}4$ months. The long duration of the light curve plateau is believed to be due to the presence of a massive ($\gtrsim 2\text{--}3 M_{\odot}$) hydrogen envelope (e.g., Falk & Arnett 1977).

After the plateau, the light curves of SNe IIP are often dominated by radioactive decay of ^{56}Co . This cobalt is the decay product of ^{56}Ni , so the luminosity at this epoch can therefore be used to estimate the amount of ^{56}Ni ejected at the explosion. Because nickel is produced in the core region, the mass of ejected ^{56}Ni provides an important probe of the core-collapse scenario itself, of the nucleosynthetic yields of SNe II and their progenitors, and of the nature of the compact central object formed at the collapse (Woosley & Weaver 1995; Woosley & Timmes 1996).

A new subclass of core-collapse supernovae has recently emerged: the narrow-line supernovae or SNe IIn (Schlegel 1990; Filippenko 1997). Like other SNe II, they show strong Balmer lines, but the lines are narrow ($\sim 1000\text{--}3000 \text{ km s}^{-1}$) and are seen in emission rather than absorption even at early times.

SN 1994W was discovered on 1994 July 29 in the Sbc galaxy NGC 4041 (Cortini & Villi 1994). Based on the presence of hydrogen lines it was quickly classified as a SN II (Bragaglia, Munari, & Barbon 1994). Subsequent spectroscopy showed that the lines had unusually narrow P Cygni profiles ($v_{\text{FWHM}} \sim 1200 \text{ km s}^{-1}$), with broad emission wings but no broad absorption component (Filippenko & Barth 1994; Cumming, Lundqvist, & Meikle 1994). Reports in IAU circulars indicated that the supernova reached a maximum of $V \sim 13.3$ around 1994 Aug 13. Further photometry by Tsvetkov (1995) showed that the supernova was a SN IIP and had a remarkably sharp drop in the B and V light curves in 1994 early November.

In this paper, we present further photometric and spectroscopic observations of SN 1994W taken on several occasions between 1994 July 31 and 1996 April 20. We focus on the low luminosity of the supernova after ~ 120 days, and interpret this as due to an exceptionally low mass of ejected ^{56}Ni . We also discuss the formation of the narrow lines.

2. OBSERVATIONS

2.1. Photometry

Our photometric data were obtained mainly in R on six occasions from 1994 November 16 to 1996 April 20, using the Jakobus Kapteyn Telescope (JKT) and the Nordic Optical Telescope (NOT) on La Palma (see Table 1). The data were bias subtracted and flat fielded using standard procedures within IRAF. Differential magnitudes between the supernova and comparison stars were measured using POLYFIT (Spännare 1997), a software package developed to do photometry on uneven backgrounds; in it, a point

spread function (PSF) is produced by fitting a Moffat function to an isolated star in the frame. This PSF and a polynomial fit to the background are then simultaneously fitted at the position of the object. For the JKT nights, a bright comparison star was in the field and was used for the relative magnitudes. For the NOT data, a fainter comparison star had to be used. Up to seven comparison stars were monitored to avoid variability. The comparison stars were calibrated against Landolt stars (Landolt 1983, 1992) at two nights on JKT and against a standard field in NGC 4147 (Christian et al. 1985) for the NOT observations. The zero point for the *R* magnitude differs slightly among the four photometric nights. We estimate a total systematic error of 0.15 mag in the *R* magnitude, including the neglect of color transformations and differential atmospheric extinction corrections, which were only applied to day 646⁴ data. For the *V* magnitude, we calibrated relative to local standards measured by Tsvetkov (1995).

The JKT observations have a rather low signal-to-noise ratio, or poor seeing, which gives large errors for the photometry, $\sim \pm 0.5$ mag. For the NOT observation (day 197) the error is smaller, and dominated by the error in the POLYFIT measurement. We estimated this error by adding to the image, using the IRAF task ADDSTAR, ten artificial stars of the same magnitude as the supernova at similar backgrounds. The rms error in the POLYFIT measurements of these stars were $\lesssim 0.15$ mag, which we regard as also being the measurement error for the supernova. A total error of 0.3 mag on day 197 is therefore rather generous and includes errors for the comparison stars. At the last observation, day 646, the supernova was not detected. We estimated an upper limit by subtracting artificial PSFs of

different brightness until a hole appeared in the background at the supernova position.

2.2. Spectroscopy

Our spectroscopic observations cover five epochs from day 18 to day 202 (see Table 2). The data were bias subtracted, flat fielded, and wavelength calibrated using IRAF. The day 31, 57, and 202 spectra were flux calibrated against a spectrophotometric standard star. The day 57 spectrum was taken at high airmass and required further corrections for slit losses. A rough flux calibration for the day 18 spectrum was obtained by comparison with contemporary visual photometry and the spectrum from day 31. The day 121 spectrum was flux calibrated using the *R* photometry from day 125.

3. RESULTS

In Figure 1 we present the light curve of SN 1994W. From the early *R* data, we estimate the date of optical outburst to have been 1994 July 14⁺²₋₄, and we label observations by number of days after this date. The light curve shows a relatively gentle rise to maximum at around 30 days, followed by a slow, plateau-like decline until ~ 110 days. The slow decline in *B* and *V* is typical of a SN IIP. At ~ 110 days, however, the supernova started to fade with unprecedented rapidity, dropping by ~ 3.5 mag in *V* in only 12 days. The fading also continued at a fast rate on the light curve tail, until our last photometric detection on day 197. We could not detect the supernova in *V* or *R* on day 646.

The spectrum of the supernova was also unusual for a SN II. Before the light curve drop, the spectra on days 18, 31, and 57 (see Figs. 2 and 3) show the strong P Cygni lines of H I, typical of a SN II, but with very narrow profiles (minima at -700 km s⁻¹ and maximum blue velocities of only 1000

⁴ Days are measured after 1994 July 14.0 (see § 3).

FIG. 1.—Observed B , V , and R light curves of SN 1994W. The data set is a compilation of our own CCD photometry (Table 1) plus photoelectric and photographic photometry compiled from Tsvetkov (1995), IAU circulars, and the observations of L. Szentasko and M. Villi (1995, private communication; *inverted triangles*). We compared Szentasko's and Villi's estimates for this supernova, and for SNs 1994D and 1994I (from the unpublished lists compiled by B. H. Granslo) with contemporary V and $B-V$ measurements when they were available. Szentasko's values for all three SNs required a correction of -0.5 ± 0.2 mag to match them with V . There was no noticeable color term. The corrected magnitudes follow the photoelectric V points well. The early R points were derived from the relative photometry of Richmond et al. (1994), using our measurement of $R = 13.96 \pm 0.15$ for their nearby calibration star (Tsvetkov's star 3).

km s^{-1}). In addition to the narrow features, the H I lines had emission wings extending out to $\sim 5000 \text{ km s}^{-1}$, a factor of $\sim 2-4$ lower than the maximum velocities normally seen in SNs II at these epochs. The H I lines were accompanied by a rich spectrum of narrow lines of low-ionization species (He I , O I , Mg II , Si II , and Fe II). Although conspicuous, the emission lines account for only $\sim 1\%$ of

FIG. 2.—Spectra of SN 1994W at 57, 121, and 202 days after explosion. The two long notches at the right of the scale show the level of zero flux at 57 and 121 days.

FIG. 3.—Evolution of the $\text{H}\alpha$ line profile of SN 1994W from day 18 to day 121. Note the near constancy of the position of the blue edge of the absorption. The three long notches at the right of the scale show the level of zero flux at 18, 31, and 57 days.

the total optical flux on days 31 and 57. Instead, a blue continuum dominates. Estimating $E(B-V) = 0.17 \pm 0.06$ from the interstellar Na I D absorption in our day 31 spectrum (Munari & Zwitter 1997), we fit it with blackbody spectra with temperatures of $\sim (1.50 \pm 0.15) \times 10^4 \text{ K}$ and $\sim (1.10 \pm 0.10) \times 10^4 \text{ K}$, respectively. The effective temperatures indicated by the blackbody fits are much higher than the $\sim 5-8 \times 10^3 \text{ K}$ usually observed in SNs IIP at similar epochs.

The decrease in temperature was accompanied by the disappearance of the He I lines and increasingly strong Fe II features. A spectrum taken by Filippenko (1997) on day 80 shows that the spectral features had changed only marginally compared to our day 57 spectrum, but the slope of the continuum indicated a decrease in effective temperature to $\sim 7-8 \times 10^3 \text{ K}$.

The photometric fading at ~ 110 days coincided with dramatic changes in the spectrum. The $B-V$ color, previously steady at 0.3 ± 0.1 , increased to 1.75 between days 85 and 111 (Fig. 1; Tsvetkov 1995). In addition, the flux in $\text{H}\alpha$ dropped at roughly the same rate as the V and R light curves. This coincidence, together with the shift to lower excitation lines during the plateau phase, suggests that the narrow lines were predominantly excited by the supernova continuum rather than by a circumstellar shock (see § 4.4).

The day 121 spectrum shows narrow ($\sim 730 \pm 120 \text{ km s}^{-1}$) emission in $\text{H}\alpha$, $\text{Na I D } \lambda 5893$, and $[\text{Ca II}] \lambda \lambda 7291, 7324$, on top of a continuum-like spectrum. The flux of the narrow $\text{H}\alpha$ component had dropped by a factor of ~ 150 since day 57. No broad features can be identified, but the sharp edge present at $\sim 5600 \text{ \AA}$ is a common feature in late-time supernova spectra, usually attributed to the redmost extent of blended Fe II or $[\text{Fe II}]$ lines. We suggest that the apparent continuum is in fact made up of overlapping broad emission lines, with a gap around 5650 \AA . Unlike other Type II events at this epoch, there is no sign of strong, broad $\text{H}\alpha$.

On day 202, the spectrum was dominated by a fairly flat, noisy continuum and unresolved $\text{H}\alpha$, which may contain a contribution from a background H II region. The flux in the

FIG. 4.—Spectrum of SN 1994W at day 202, with continuum subtracted. The solid line (not a fit to the spectrum) shows Gaussian profiles of width 4500 km s^{-1} at the positions of [O I] $\lambda\lambda 6300, 6364$, H α , and [Ca II] $\lambda\lambda 7291, 7323$ in the ratio 3:1:2.5:3:2.

narrow H α line had dropped by a factor of $\gtrsim 5$ compared to the day 121 spectrum, but its width remained constant within the errors. The flux in the R band of our spectrum on day 202 agrees well with our R magnitude on day 197. Our photometric limit from day 646 ($R > 22$) demonstrates that the supernova continued to fade after day 202, and gives a lower limit of $\sim 50\%$ for the flux contribution of the supernova to the day 202 spectrum. We suggest that the continuum at this epoch comes from background stars. We tentatively identify the broad, $v_{\text{FWHM}} = (4.5 \pm 1.5) \times 10^3 \text{ km s}^{-1}$ emission feature at $\sim 7350 \text{ \AA}$ as [Ca II] $\lambda\lambda 7291, 7324$, and suggest that the emission remaining after the continuum is subtracted is composed of broad emission lines, as on day 121. The [Ca II] feature has a luminosity that is a factor of ~ 100 lower than for SN 1987A at the same epoch; the luminosity of H α is at least a factor of 2 lower still (Fig. 4).

4. DISCUSSION

In Figure 5 we compare the absolute light curve of SN 1994W to those of other SNs IIP, SN 1987A, and the luminous SN IIL (linear) 1979C. At maximum, SN 1994W was as luminous as SN 1983K, the most luminous SN IIP previously observed (Phillips et al. 1990). Also evident in Figure 5 are the rapid fading and low luminosity of SN 1994W after the plateau phase ends, i.e., ~ 110 days, and the fast decline after that. We now investigate whether the unusual light curve and spectra of SN 1994W can be explained in terms of standard supernova theory.

4.1. The Mass of Ejected ^{56}Ni

For a SN IIP, the mass of ejected ^{56}Ni , $M_{\text{ej},56}$, can be estimated from the luminosity after the plateau phase ends. At this point, the optical emission is powered by γ -ray energy deposited into the ejecta from the radioactive decay of ^{56}Co , the decay product of ^{56}Ni . The e -folding time for the cobalt decay is 111.26 days, so the radioactive decay creates a tail to the bolometric light curve with a slope of $0.00976 \text{ mag day}^{-1}$, if all the γ -rays are trapped. When other contributions to the light curve have been accounted for, the luminosity of the tail gives a measure of $M_{\text{ej},56}$.

The mass of ejected nickel has been determined in this way for a handful of SNs IIP, for example SNs 1969L

FIG. 5.—Absolute light curves of SN 1994W compared with selected other Type II supernovae. We adopt 25.4 Mpc for the distance to SN 1994W (taking the recession velocity of 1231 km s^{-1} from Tully [1988] and adopting $H_0 = 65 \text{ km s}^{-1} \text{ Mpc}^{-1}$ with the Virgo infall model of Kraan-Korteweg [1986]). Using the relations of Munari & Zwitter (1997) for the strength of interstellar Na I absorption, we estimated the extinction toward SN 1994W to be $E(B-V) = 0.17 \pm 0.06$. For the other SNs, the following original data were adopted: for SN 1969L, distance 11 Mpc, A_V 0.19 mag (Schmidt et al. 1993); for 1979C, 16.1 Mpc, 0.45 mag (Ferrarese et al. 1997); for 1987A, 50 kpc, 0.15 mag (Suntzeff & Bouchet 1990); for 1990E, 21 Mpc, 1.5 mag (Schmidt et al. 1993); for 1991G, 15.5 Mpc, 0.025 mag (Blanton et al. 1995).

($0.07 \pm 0.03 M_\odot$; Schmidt et al. 1993), 1990E ($0.073^{+0.018}_{-0.051} M_\odot$; Schmidt et al. 1993), 1992H ($\sim 0.075 M_\odot$; Clocchiatti et al. 1996), and SN 1991G ($0.024^{+0.018}_{-0.010} M_\odot$; Blanton et al. 1995).

Our method for estimating the $M_{\text{ej},56}$ of SN 1994W is to compare the level of its luminosity in R after the plateau to that of SN 1987A at similar epochs. We chose SN 1987A as a template because its distance and extinction are well known, and because its light curve was entirely powered by radioactive decay as soon as a few days after explosion. SN 1987A also resembled a SN IIP in having a massive hydrogen envelope (Woosley 1988). For SN 1987A, the value of $M_{\text{ej},56}$ was $\sim 0.071^{+0.019}_{-0.016} M_\odot$ (Suntzeff & Bouchet 1990).

One problem with our method is that the light curve tail of SN 1994W declines much faster than the decay rate of ^{56}Co . We must therefore be careful in spelling out the assumptions involved in interpreting the light curve. We identify two possible scenarios that can lead to such a decline, and that lead to different estimates of $M_{\text{ej},56}$. Radioactive decay of ^{56}Co could dominate, but be unable for some reason to maintain the standard tail of the R light curve. Alternatively, some source other than ^{56}Co decay may dominate the light curve during this period. In the following sections we investigate both of these possibilities and their implications for $M_{\text{ej},56}$.

4.2. The Steep Decline of the Late Light Curve: Implications for the Nickel Mass

First, we consider the possibility that all of the flux in the tail is indeed due to cobalt decay. The steep decline could then be the result of increasing escape of γ -rays, a gradual

shift of the spectrum from the optical to the infrared, or increasing dust obscuration.

Assuming a central radioactive source, the optical depth to γ -rays through the ejecta decreases with time as $\tau_\gamma = (t_1/t)^2$, where t_1 is the time when $\tau_\gamma = 1$. In SN 1987A, $t_1 \sim 750$ days (Kozma 1996). Taking into consideration the fact that $\sim 3.5\%$ of the cobalt decay energy is mediated by positrons and therefore deposited locally, the bolometric luminosity decays by a factor $f_{\text{leak}} = 1 - 0.965 \exp(-\tau_\gamma)$ in addition to the decay of ^{56}Co . The observed flux in R between days 125 and 197 drops by a factor $f_{\text{obs}} = 6.6^{+7.2}_{-3.5}$ in addition to cobalt decay. With the assumptions above, the maximum value of f_{leak} for the same period is only 2.0 (for $t_1 \sim 77$ days) and thus cannot reproduce the fast decline of the light curve. We therefore believe that γ -ray leakage was not the cause of the exceptionally fast fading of SN 1994W after ~ 120 days.

A gradual shift of the spectrum into the infrared might be expected if the mass of ^{56}Ni was substantially lower than in SN 1987A, and if the reduced radioactive heating lowered the ejecta temperature. In this scenario, our assumption of linear scaling between $M_{\text{ej},56}$ and the R -luminosity could break down. To test this numerically, we ran two models of SN 1987A kindly provided for us by C. Kozma. These models do not include dust formation and are similar to her mixed 10H model, as detailed in Kozma (1996), but with $M_{\text{ej},56} = 0.001(0.01) M_\odot$ and other radioactive isotopes decreased accordingly. We find that on day 150, more than 60 (70)% of the line emission comes out between 3000 and 9000 Å, $\sim 7.3(5.3)\%$ and $\sim 6.6(2.2)\%$ of which is in H α and [Ca II], respectively. Therefore, if dust formation is unimportant and the structure is similar to that of SN 1987A, linear scaling of $M_{\text{ej},56}$ with R and V luminosities seems to be valid down to very low values of $M_{\text{ej},56}$.

The situation is different if dust formation is important. We expect that below some value of $M_{\text{ej},56}$, radioactive heating of the ejecta will be unable to prevent the formation of dust. This could attenuate and shift the supernova emission into the infrared already shortly after the plateau phase. This effect could be further amplified by increased molecular cooling, since the destruction rate of molecules will decrease with lower $M_{\text{ej},56}$. We know that dust increased the cooling and obscured the line-emitting region in SN 1987A (see Kozma 1996 and references therein), albeit at a later epoch (between ~ 350 and 600 days) than considered here for SN 1994W. The dust-covering factor would have increased with time, creating a blueshift of the supernova lines, as observed for SN 1987A (Danziger et al. 1991). Our day 202 spectrum is too noisy to reveal such an effect. Thus, we cannot rule out dust formation as the cause of the fast fading in R .

To obtain an estimate of $M_{\text{ej},56}$ in the case of early dust formation, we choose the R measurement from day 139, which is the first photometric point on the light curve tail. This gives $M_{\text{ej},56} = 0.015^{+0.012}_{-0.008} M_\odot$. The estimated error includes the statistical error shown in Figure 1, uncertainty in the distance modulus of SN 1994W (± 0.3 mag), the extinction toward the supernova (± 0.15 mag), and the estimated systematic error of our R calibration (± 0.15 mag).

This $M_{\text{ej},56}$ is slightly lower than that of the previous record-holder, SN 1991G, which had $0.024^{+0.018}_{-0.010} M_\odot$. However, SN 1991G did not show the very steep decline of the light curve tail (Blanton et al. 1995). This could mean that even SN 1991G ejected too much ^{56}Ni to allow early

dust formation, although the structure of SN 1991G could also have been less favorable for dust formation than that of SN 1994W.

If the steep tail is not primarily powered by radioactive decay, we need an additional, fast declining, energy source. A light echo seems rather improbable, as this would produce a spectrum in the tail that is qualitatively similar to the spectrum at the peak. This is not observed. One possible power source is interaction of the ejecta with circumstellar material at $\gtrsim 110$ days. In § 4.4 we present evidence from the narrow-line profiles for a thin, dense circumstellar shell close to the supernova. The high density we find for the shell may be sufficient to set up the isothermal shock wave scenario discussed by Grasberg & Nadyozhin (1986), in which the ejecta's kinetic energy is transformed to UV and optical emission. As the shell is accelerated, the conversion of kinetic energy becomes less efficient, which could create the steeply falling light curve. Another explanation for the steep decline of the tail is that it is dominated by diffusion of thermal energy from the mantle region. Weaver & Woosley (1980) found that a residual flux, dropping at roughly the same rate as we find for SN 1994W, may be present even when there is no ^{56}Ni ejected at the explosion. In either case, the photometric point on day 197 gives a firm upper limit to $M_{\text{ej},56}$. Assuming no dust, trapped γ -rays, and a linear scaling between R -luminosity and $M_{\text{ej},56}$, this gives $M_{\text{ej},56} \lesssim 0.0026^{+0.0017}_{-0.0011} M_\odot$. This limit could of course be higher if dust is also important in these scenarios.

In summary, we suggest that the low luminosity on the light curve tail is due to a very low mass of ejected nickel.

4.3. The Progenitor and the Nature of the Collapsed Core

We will now examine whether such a small mass of ^{56}Ni would be consistent with the type of progenitor indicated by the light curve up to ~ 110 days. The very low nickel mass we find, if radioactivity is not the prime power source between days 120 and 197 ($M_{\text{ej},56} \lesssim 0.0026^{+0.0017}_{-0.0011} M_\odot$), only agrees with model calculations for progenitors in the ranges $M_{\text{ZAMS}} \sim 8\text{--}10 M_\odot$ (Mayle & Wilson 1988) and $M_{\text{ZAMS}} \gtrsim 25 M_\odot$ (Woosley & Weaver 1995). If the steep decline of the light curve tail is due instead to early dust formation, our more conservative estimate ($M_{\text{ej},56} = 0.015^{+0.012}_{-0.008} M_\odot$) is still lower than the range of $M_{\text{ej},56} \sim 0.04\text{--}0.20 M_\odot$ predicted for progenitors with $M_{\text{ZAMS}} \sim 11\text{--}25 M_\odot$ (Woosley & Weaver 1995), but somewhat higher than $M_{\text{ej},56}$ predicted for stars with $M_{\text{ZAMS}} \sim 8\text{--}10 M_\odot$ (Mayle & Wilson 1988).

Theory thus favors two kinds of progenitor that eject low masses of ^{56}Ni , a low-mass progenitor that produces almost no nickel during the explosion or a very massive star in which the mass cut (the location in mass coordinates between ejected matter and matter eventually forming the compact, central object) is situated sufficiently far out for most of the synthesized nickel to be trapped in the compact object. Because of the extensive fallback of material in the latter case, the mass of the compact object may become large enough to form a black hole (Woosley & Timmes 1996). As a matter of fact, Woosley & Timmes (1996) suggest that the prime observational diagnostic of a supernova forming a black hole would be a bright supernova that plummeted to very low or zero luminosity right after plateau.

To estimate the mass of the progenitor, we use the early light curve (i.e., at $t \lesssim 110$ days) of the supernova. At this

epoch, the supernova is powered by the release of stored shock energy from the explosion. The physics of the plateau phase has been parameterized analytically (Popov 1993) and fitted to numerical simulations (Litvinova & Nadyozhin 1985) in terms of the explosion energy E , the stellar radius R_0 , and the mass of the hydrogen envelope at the time of explosion, M_{env} . Assuming a canonical value for E in the range $1.0\text{--}1.5 \times 10^{51}$ ergs, we use parameterized expressions to estimate R_0 and M_{env} for given t_d (the epoch when the plateau ends) and V (the absolute visual magnitude before turn-down). Taking $t_d \sim 110$ days and $V = -17.7 \pm 0.5$, Popov's expressions give $M_{\text{env}} \sim 7\text{--}13 M_\odot$ and $R_0 \sim 0.5\text{--}2.0 \times 10^{14}$ cm, while the numerical models of Litvinova & Nadyozhin (1985) give $M_{\text{env}} \sim 11\text{--}19 M_\odot$ and $R_0 \sim 0.4\text{--}1.2 \times 10^{14}$ cm. M_{env} decreases with increasing R_0 for given V and E . We thus derive a value of M_{env} that is similar to, or in the case of the numerical models, slightly higher than that of SN 1987A (Woosley 1988; Shigeyama & Nomoto 1990).

Such high values of M_{env} strongly favor a higher mass range ($M_{\text{ZAMS}} \gtrsim 25 M_\odot$) for the progenitor of SN 1994W. To M_{env} we need to add the mass of the helium- and metal-rich core at the time of explosion. For a progenitor with $M_{\text{ZAMS}} = 25 M_\odot$, this is $\sim 9 M_\odot$ (Woosley & Weaver 1995). To be consistent with our estimate of M_{env} for a progenitor with $M_{\text{ZAMS}} = 25 M_\odot$, we must therefore allow for $3\text{--}9 M_\odot$ of stellar winds if Popov's expressions are used for the plateau, while the numerical models do not require presupernova mass loss.

A low-mass ($M_{\text{ZAMS}} \sim 8\text{--}10 M_\odot$) progenitor is possible for SN 1994W, but only if the explosion energy was lower than the canonical $1.0\text{--}1.5 \times 10^{51}$ ergs assumed above and the conversion of explosion energy to radiation was very efficient. Model B of Falk & Arnett (1977) shows that a high ($> 30\%$) efficiency is possible if the star is very extended ($R_0 = 9.25 \times 10^{14}$ cm). Assuming an explosion energy as low as 3×10^{50} ergs, Popov's model can give an envelope mass of only $\sim 3.5 M_\odot$ for a radius of 5×10^{14} cm, while the model of Litvinova & Nadyozhin (1985) gives $\sim 5.0 M_\odot$ for a radius of 3×10^{14} cm. Both the analytical and numerical estimates are thus consistent with a low-mass ($M_{\text{ZAMS}} \sim 8\text{--}10 M_\odot$) progenitor if the progenitor is very extended and the explosion energy is low. Because a $M_{\text{ZAMS}} \sim 8\text{--}10 M_\odot$ supernova only ejects $M_{\text{ej},56} \sim 0.002 M_\odot$ (Mayle & Wilson 1988), this type of explosion is only consistent with our lowest value of $M_{\text{ej},56}$ (see § 4.2).

If SN 1994W resulted from the explosion of an $8\text{--}10 M_\odot$ star, its compact object should be a neutron star. If its progenitor was instead in the higher mass range, the mass of the newly created compact object could be large enough to form a black hole (Woosley & Timmes 1996). For a $25 M_\odot$ progenitor, the mass cut should be $\gtrsim 2.1 M_\odot$ (Timmes, Woosley, & Weaver 1996). The maximum mass of a neutron star is rather uncertain, depending on the adopted equation of state. If it is as low as $\sim 1.5\text{--}1.6 M_\odot$ (Brown & Bethe 1994), such a massive progenitor of SN 1994W has most likely formed a black hole.

4.4. The Narrow Lines

The narrow lines of SN 1994W are not typical of SNs IIP. In § 3 we argued that the flux in the lines was too low to affect the light curve on the plateau, which is why we were able to apply the light curve analysis in § 4.3. Here we discuss the origin of the narrow lines. As already suggested

in § 3, the lines can be naturally explained in terms of excitation by the hot supernova continuum. Another explanation could be excitation caused by circumstellar interaction of the ejecta with a clumpy wind, as suggested for SN 1988Z by Chugai & Danziger (1994). However, we see no obvious reason why this excitation mechanism should result in an excitation of the lines that closely follows the fading of the supernova continuum, as in SN 1994W.

The narrow emission lines were present as early as day 17–18 (Bragaglia et al. 1994; Cumming et al. 1994). H α had a roughly constant P Cygni profile from then until at least day 57, the epoch of our last spectrum on the plateau (see Fig. 3). The emission part of the P Cygni profile has a rounded rather than flat-topped peak, which immediately indicates that the line-of-sight optical depth in the lines $\gg 1$ (Mihalas 1978). Furthermore, the steep red side and relatively broad absorption trough observed in both H I and Fe II indicate that the lines were scattering-dominated, and originated in a rather thin shell ($\Delta R/R < 1$) located close to the photosphere (see Fransson 1984). The optical thickness of the Fe II lines allows us to put a limit on the density in the shell. Assuming a gas temperature of 10^4 K and Fe II/H = Fe/H = 4×10^{-5} (i.e., the solar value of Fe/H), we use expressions from Mihalas (1978) to obtain a hydrogen density of $n_H \gtrsim 3 \times 10^8 v_3 r_{15}^{-1} \text{ cm}^{-3}$. Here v_3 is the velocity of the shell in units of 10^3 km s^{-1} and r_{15} is the shell radius in units of 10^{15} cm. We know from the line profiles that $v \sim 10^3 \text{ km s}^{-1}$, and that the shell radius must be close to that of the photosphere. From our blackbody fits (see § 3), we estimate that the photospheric radius on days 31 and 57 was $\sim 8.5 \times 10^{14}$ cm and $\sim 1.1 \times 10^{15}$ cm, respectively. This gives a limit on $n_H \gtrsim 3 \times 10^8 \text{ cm}^{-3}$, quite consistent with the absence of forbidden lines in the spectrum during the plateau.

The near constancy of the shell's velocity up to day 57 and its proximity to the photosphere allow us to locate the starting radius of the shell, r_0 , assuming that the same shell emits the lines at all epochs. Using $v_3 = 1$, we obtain $r_0 \sim 6 \times 10^{14}$ cm from both the day 31 and the day 57 data. Because the radius of the photosphere is rather uncertain ($\sim \pm 30\%$), so is r_0 .

The shell appears to have been quite close to the supernova around the time of explosion. We identify two possible origins. One possibility is that the shell was created in the supernova envelope during the explosion. The formation of such a shell was suggested by Falk & Arnett (1977), who in fact also predicted that this should result in narrow P Cygni profiles. The problem with this interpretation is the low velocity of the shell. Even in their extended, low explosion energy model B, Falk & Arnett (1977) find a shell velocity roughly twice as high as we found for SN 1994W.

It seems more plausible that the shell was circumstellar, perhaps the result of an episode of increased mass loss some time $t = (r_0 - R_0)/v_{\text{sh}}$ prior to the explosion, where v_{sh} is the initial velocity of the shell. This scenario is similar to the model presented by Grasberg & Nadyozhin (1986) for SN 1983K. We find that radiation from the supernova can easily accelerate the shell to the observed velocity. Assuming pure electron scattering, a shell initially at rest is accelerated up to $v \sim 8.9 \times 10^2 L_{50} r_{15}^{-2} \text{ km s}^{-1}$, where L_{50} is the integrated bolometric luminosity of the supernova in units of 10^{50} ergs and r_{15} is the shell radius in units of 10^{15} cm. The velocity can be substantially higher if line acceleration is important. We note that the blue edge of the H α

absorption shifted slightly to the blue between days 18 and 31, corresponding to an increase in shell velocity from $997 \pm 30 \text{ km s}^{-1}$ to $1063 \pm 15 \text{ km s}^{-1}$ (Fig. 3). This is consistent with supernova radiation continuing to accelerate the shell between these epochs.

In the model of Grasberg & Nadyozhin (1986), the shell is eventually accelerated to the velocity of the supernova ejecta through circumstellar interaction. However, in reality this may take longer than in Grasberg & Nadyozhin's (1986) 1-D models, since the slow shell might break up (Falk & Arnett 1977). In SN 1994W, the disruption of the proposed shell by the ejecta could perhaps power the light curve between ~ 120 and 197 days, as we suggested in § 4.2.

5. CONCLUSIONS

We have observed the luminous SN 1994W. We find that the low flux of the supernova after ~ 120 days is evidence of a very low mass of ^{56}Ni ejected at the explosion; in fact, the lowest inferred for any SN II.

The estimated mass of ^{56}Ni depends on the interpretation of the unusually rapid fading observed in R between days 120 and 197. Either the supernova ejected $0.015^{+0.012}_{-0.008} M_{\odot}$ of ^{56}Ni , or the nickel mass could have been as low as $\leq 0.0026^{+0.0017}_{-0.0011} M_{\odot}$. The first possibility requires inefficiency in converting radioactive decay energy to R luminosity, and we find that early dust formation is the most likely cause for this. Alternatively, the primary power source between 120 and 197 days may not have been radioactive decay, but perhaps interaction with a thin circumstellar shell, or diffusion of energy in the mantle. In this case, $M_{\text{ej},56} \sim 0.0026^{+0.0017}_{-0.0011} M_{\odot}$ is an upper limit, if dust formation was unimportant.

Two types of progenitor seem consistent with the low nickel content and high luminosity of the supernova before the end of its plateau phase. The first possibility is a low-

mass progenitor having a $M_{\text{ZAMS}} \sim 8\text{--}10 M_{\odot}$, a very extended envelope, and a low explosion energy, $E \sim 3 \times 10^{50}$ ergs. As a low-mass progenitor would only produce $\sim 0.002 M_{\odot}^{56}\text{Ni}$ (Mayle & Wilson 1988), consistent only with our lowest value for $M_{\text{ej},56}$, an additional power source, presumably circumstellar interaction or diffusion of energy stored in the mantle, is needed to explain the light curve between 120–197 days for this type of progenitor. However, the energy budget seems uncomfortably tight for the low-mass case, as SN 1994W was one of the most luminous supernovae observed.

A more natural possibility is therefore a high-mass progenitor with $M_{\text{ZAMS}} \gtrsim 25 M_{\odot}$, which could have lost a few solar masses as stellar winds and exploded with the canonical energy $1.0\text{--}1.5 \times 10^{51}$ ergs. This type of progenitor is consistent with both of our estimates of $M_{\text{ej},56}$. Such a supernova should have a mass cut of $\gtrsim 2.1 M_{\odot}$, sufficient to trap most of the produced ^{56}Ni , and could have formed a black hole.

Finally, we find that the narrow lines were likely formed in a thin, circumstellar high-density shell close to the supernova, accelerated by radiation from the supernova.

We thank P. Rudd, R. Rutten, M. Breare, and E. Harlaftis for taking service observations, E. Zuiderwijk for giving up PATT time to take the day 18 spectrum, and M. Näslund for taking part in our last observation of the supernova. We are especially grateful to C. Kozma, B. Leibundgut, and S. Blinnikov for important discussions, and to L. Szentasko and M. Villi for access to unpublished data. We also thank M. Pérez-Torres for early analysis of the narrow lines and S. Spännare for help with photometry measurements. This research was supported by the Swedish Natural Science Research Council. J. S. and P. L. also acknowledge support from the Swedish National Space Board.
